(Dated: October 14, 2016)

Liquid argon time projection chambers (LArTPCs) produce remarkable fidelity in the observation of neutrino interactions. The superior capabilities of such detectors to reconstruct the spatial and calorimetric information of neutrino events have made them the detectors of choice in a number of experiments, specifically those looking to observe electron neutrino (ν_e) appearance. The LArTPC promises excellent background rejection capabilities, especially in this “golden” channel for both short and long baseline neutrino oscillation experiments. We present the first experimental observation of electron neutrinos and anti-neutrinos in the ArgoNeuT LArTPC, in the energy range relevant to DUNE and the Fermilab Short Baseline Neutrino Program. Additionally, we present a demonstration of separation of electrons from gammas using neutrino data.

I. INTRODUCTION

The confirmation of neutrino oscillations [1, 2] has transformed the field of experimental neutrino physics. Subsequent measurements of neutrino oscillation parameters, mixing angles and mass splittings [3–5], have pushed neutrino physics into the realm of precision measurements. Neutrino physics continues to provide exciting new discoveries and is a promising avenue to probe physics beyond the standard model. Neutrino experiments are set to measure CP violation in the lepton sector [6, 7] as well as

the mass ordering of neutrinos [8], both of which will require high power neutrino beams oscillating over long baselines. The short-baseline neutrino anomalies, which may be consistent with the existence of light sterile neutrinos [9–12], may be resolved by neutrino experiments observing oscillations at short baselines (such as the Short Baseline Neutrino Program [13]), along with the measurements of other experiments [14–16]. Many of these experiments share an experimental signature: the appearance of electron-neutrinos (ν_e) from an initially muon-neutrino (ν_μ) beam [7, 13].

In such oscillation measurements the flavor of the neutrino is determined by charged current (CC) interactions of the neutrino, which in the case of electron-neutrinos results in an elec-

* corey.adams@yale.edu

tron in the final state. The number of detected events is then compared with the expectation, determined from beam simulations (which can be well constrained from ν_μ measurements [17]) or by scaling events observed in a near detector. An excess of electron like events over the expectation could signify ν_e appearance in the form of neutrino oscillations from ν_μ to ν_e .

The searches for CP-violation and a light sterile neutrino require high precision measurements of ν_e appearance. However, the small interaction rate of neutrinos makes maximizing the detection of electron neutrinos and suppression of background signals essential. Historically, in experiments like MiniBooNE, a Cherenkov Imaging Detector [18], a main background for CC ν_e events is neutral current interactions, which produce π^0 mesons equally for each neutrino flavor. The π^0 mesons decay preferentially into pairs of energetic gammas. These gammas are hundreds of MeV for the Booster Neutrino Beam [13, 18, 19], for example. A gamma, at typical neutrino beam energies, converts primarily through pair production - see Figure 1. Gammas can appear almost identical to electrons in most neutrino detector technologies, especially in the case that the two electromagnetic showers overlap or one of the gammas escapes the detector before interacting. A successful measurement of CP violation and resolution of short-baseline anomalies in neutrino physics requires high discrimination power between electron neutrinos and high energy gamma backgrounds.

Liquid argon time projection chamber (LArTPC) [20, 21] technology provides excellent electron neutrino detection and electron/gamma separation. The primary method of discrimination between electrons and gammas exploits the radiation length ($X_0 = 14$ cm) in argon, which is large compared to the excellent spatial resolution of TPCs. This means that a gamma can leave a visible gap between its origin and the place in the TPC where it interacts, as described more fully in Section IV. For an electron originating from a CC ν_e interaction no such gap will be present. This paper applies this topological selection to

identify a pure sample of low energy electron neutrino events in a liquid argon time projection chamber. We have identified the first sample of these events (37 electron neutrino candidates), with a purity estimated at $80 \pm 15\%$.

Figure 1. The cross section of high energy gammas on argon between 1 MeV and 1 GeV. Most gammas produced by neutrino interactions relevant to DUNE [7] and the SBN Program [13] are in this region. Here, κ refers to the pair production cross section for the nuclear field and electron field. Pair production becomes the dominant cross section above 10 MeV. Data obtained from the Xcom database [22].

High energy gammas can, in some cases, interact at a sufficiently short distance from the neutrino's interaction vertex such that the gap from the vertex is not visible. Section IV examines this gamma interaction distance in more detail. Further, the hadronic activity at the vertex could be invisible in the TPC data, either because it consists of only neutral particles or because the particles are below detection threshold. Without the presence of hadronic activity to distinguish the neutrino interaction vertex, it is not possible to observe a gap. In this case, a second method of electron/gamma discrimination has been proposed which uses calorimetry at the start of the electromagnetic (EM) shower. An electron produces ionization consistent with a single ionizing particle, whereas the electron/positron pair produced by a gamma conversion produces ionization consis-

tent with two single ionizing particles.

The calorimetric discrimination of electrons from gammas through the measure of ionization/distance is frequently referred to as dE/dx discrimination. Though this type of technique has been used in previous neutrino experiments [23–25], this work presents the first demonstration of the feasibility of this method for discriminating electrons and gammas originating from neutrino interactions in liquid argon.

II. THE ARGONEUT DETECTOR

The ArgoNeuT detector [26] ran in the NuMI (Neutrinos from the Main Injector) beamline at Fermilab, outside of Chicago, IL, for six months in 2009-2010. The detector had an active volume of $47 (w) \times 40 (h) \times 90 (l) \text{ cm}^3$ resulting in an active mass of 170 L of liquid argon. The detector was instrumented with two planes of 240 sense wires, spaced 4 mm apart, sampled every 198 ns. The wires were mounted at -30° and $+30^\circ$ to vertical and a third, non-instrumented plane, placed between the active volume and the wire planes, acted as a shielding plane. ArgoNeuT was installed directly in front of the MINOS near detector [3], which has provided muon spectrometry for many ArgoNeuT analyses [27]. For more details on the construction and operation of the ArgoNeuT detector see [26].

The NuMI beamline [28] is the higher energy of the two neutrino beams produced at Fermilab. The beam is capable of running in neutrino and anti-neutrino modes, depending on the polarity of the magnetic field applied in the focusing magnetic horn system. During the ArgoNeuT data taking, NuMI was running in the low energy mode, with the mean energy $\langle E_{\nu_\mu} \rangle = 9.6 \text{ GeV}$, $\langle E_{\bar{\nu}_\mu} \rangle = 3.6$ ($\langle E_{\nu_\mu} \rangle = 4.3 \text{ GeV}$ in neutrino mode). Although the beam consists mainly of muon neutrinos and anti-neutrinos there is a small ($\sim 2\%$) contamination of electron neutrino and anti-neutrino events, with an energy spectrum shown in Figure 11. This allows the study of electron neutrino interactions. Data presented here were taken in both

neutrino (8.5×10^{18} Protons on Target) and anti-neutrino mode (1.20×10^{20} Protons on Target).

III. EVENT SELECTION

In order to demonstrate the calorimetric separation of electron-like events from gamma-like events, high purity samples of both electrons and gammas must be selected. A sub-sample of the ArgoNeuT data set containing electromagnetic showers is isolated first through an automated procedure, and this sub-sample is used to select well defined electron and gamma events by visual scanning.

Figure 2. Principal Component Eigenvalue (top) and “Modified hit density” (bottom) calculated for single electron showers (red) and muon tracks (blue).

Selecting the sub-sample of electromagnetic showers is based on information from the 2-dimensional clusters of charge depositions (hits) in each wire plane. First, empty events and events with only track like particles are removed

from the sample using an automated filter. This filter considers two-dimensional clusters of hits made with the LArSoft package [29], and calculates several parameters of these clusters to differentiate between track-like and shower-like clusters.

The two most successful metrics in separating tracks and showers are the principal eigenvalue of a principal component analysis (PCA), and a direction corrected hit density of the cluster:

- **Principal Component Eigenvalue:** A principal component analysis (PCA) [30] takes a collection of N-dimensional points and numerically finds the orthonormal coordinate system that best aligns to the data. The goodness-of-fit metrics in the PCA analysis are the eigenvalues of the transformation matrix between the initial coordinate system and the best fit. In this analysis, we use the 2D reconstructed charge depositions (hits) in the wire-time views of the collection plane TPC data and perform a principal component analysis on each cluster. For track like particles, which have strong directionality, the first eigenvalue of PCA is quite high, close to 1. For shower like clusters, the direction of the shower and its transverse direction are less obviously separated, and the principal eigenvalue is lower than 1.
- **Direction Corrected Hit Density:** A showering event is identified by significant activity in the TPC that is resolved away from the primary axis of the particle. That is, a shower has many hits reconstructed as it travels through the TPC, whereas a track generally has one charge deposition detected per step through the TPC. Measuring the hit density along a particle, defined as hits per unit distance, can thus discriminate between tracks and showers. Since hits are only reconstructed on wires, the hit density is corrected to account for the fact that high angle tracks and showers (more parallel to the wires) have relatively fewer hits reconstructed.

Figure 2 shows these separation parameters

obtained using Monte Carlo simulations of single electrons as a model for electromagnetic showers, and single muons and protons as an archetype for tracks. To select electromagnetic showers, a cut is made on the value of $\log(1 - E.V_{PCA}) > -5$ (see Figure 2 (top)). $E.V_{PCA}$ is the first eigenvalue of the PCA analysis. This corresponds to rejecting all clusters that have a principal eigenvalue greater than ~ 0.999 . A second cut is made on the corrected hit density to reject track like events. Events with a corrected hit density greater than 1.5 hits per cm are kept (see Figure 2 (bottom)).

An additional requirement is that a shower-like cluster in one plane should correspond to an analogous cluster in the second plane at the same drift time. This removes spurious events tagged as showers due to wire noise or other sources in just one plane.

To remove events which resulted in a large amount of total charge, an additional set of criteria is applied using all of the hits in a single view in an event as a single cluster. These criteria remove high-multiplicity ν_μ deep inelastic scatter events.

This procedure resulted in a sample of ArgoNeuT events that contained an enhanced fraction of electromagnetic shower events, from which the final electron and gamma samples are identified through topological selection.

IV. TOPOLOGICAL SELECTION OF ELECTRONS AND GAMMAS

When a gamma is produced in an interaction in argon, it will travel some distance, typically less than 50 cm (for a 500 MeV gamma), before it interacts and induces an electromagnetic shower. Thus there is often a gap between the origin of the gamma and the start of the electromagnetic shower. If there is other activity in the detector at the location of the gamma production, the gap can be detected and the gamma can be classified.

The distribution of conversion distances for gammas in the energy range typical of the gammas used in this analysis is shown in Figure 3.

Figure 3. The conversion distance of each gamma in the Monte Carlo sample used for this analysis, which is about 7000 gammas in the energy range of several hundred MeV, as modeled by GEANT4 [31].

There are gammas that convert very close to the generation point (here, 7% of the gammas convert within a centimeter). The definition of “too close” depends on the analysis being performed, however, there will always be a fraction of gammas for which a topological based cut is insufficient to tag them as gammas. In the ArgoNeuT detector, the minimal resolution for a gamma gap is approximately one wire spacing (4 mm). In neutrino interactions with hadronic activity at the vertex it is possible that other particles can obscure the start of an electromagnetic shower. In this case, even gaps as large as a few centimeters can become unidentifiable.

We have chosen to define two types of topologies as gamma candidates, based on the observation of charged protons or pions at the neutrino interaction vertex: electromagnetic showers pointing back to charged particle activity at a vertex, implying hadronic activity, and neutral current π^0 events where two electromagnetic showers project back to a common point. In the second case, hadronic activity at the vertex is allowable but not required, and both electromagnetic showers are used in the analysis. Example gamma interactions are shown in Figure 4. Gammas that we are unable to positively identify through only topological considerations - if, for example, the electromagnetic shower is the only activity in the detector - are removed from the data set entirely.

For a sample of electrons, this analysis targets

Figure 4. Example of an event with two gamma candidate.

electron neutrino events as the electron shower candidates. To maximize purity, an electromagnetic shower is selected as an electron candidate only in events that also exhibited hadronic activity at the vertex *without* the presence of a gap between the shower and other particles. In addition, events with a track-like particle matched to a muon in the MINOS near detector are rejected. This suppresses the ν_μ charged current events in which the muon radiates significantly. An example of an electron candidate event is shown in Figure 5.

Figure 5. Example of a ν_e CC event.

In total, 37 electron candidate showers and 274 gamma candidate showers are selected for the present analysis.

V. ELECTROMAGNETIC SHOWER RECONSTRUCTION

The first step in the reconstruction chain is to remove effects of electronics response and field response and remove the coherent and electronics noise. This is done on a wire-by-wire basis using a Fast Fourier Transform based deconvolution kernel. A signal peak finding algorithm is then used to find charge depositions on each wire, reconstructed as hits. The integral of the ADC count in each hit is used to calculate the charge dQ using an $(\text{ADC} \times \text{Timetick})/\text{Charge}$ conversion constant. These constants are obtained using through-going muon events in a way analogous to [27], for every wire individually, on both collection and induction planes. To determine the constants, all of the muon hits on each wire are fit with a Gaussian-convolved Landau distribution. The conversion constant is adjusted until the most probable value of the Landau distribution is 1.73 MeV/cm, the expected theoretical value [27].

The dQ of each hit is corrected to account for the electron lifetime with an exponential formula $e^{-\frac{t_{drift}}{\tau}}$, where τ is the measured electron lifetime for each ArgoNeuT data run (typically 500 to 800 ms) and t_{drift} is the time each charge deposition took to drift to the wires, calculated from its position in the TPC. The drift time, t_{drift} , is known from synchronizing the ArgoNeuT readout window with the NuMI beam timing. The measured charge deposition dQ is also corrected for the recombination of electrons and ions as parameterized in [32].

The hits for each candidate shower are re-assembled into clusters using a scanning tool and fed into a shower-reconstruction algorithm. This allows the refinement of the start point and direction in each plane for events with busy topologies. In particular, for some events with overlapping protons and pions at the start of the shower, hits from the hadronic particle are excluded from the dE/dx calculation. This procedure is only done when the hadronic activity obscures a significant portion of the electromagnetic shower. One quarter of the electron candidate sample had protons and pions obscuring

the shower, in total.

In order to measure dE/dx correctly, it is important to precisely determine the start point and direction of the shower. In particular, the start point and direction are needed to measure the *first* several centimeters of the shower before the development of the electromagnetic cascade. Once the shower develops, the electron and gamma populations become significantly less distinguishable (see Appendix B). The details and validation of the electromagnetic shower reconstruction algorithms are available in Appendix A.

Figure 6. The effective pitch for the electron and gamma samples, data.

For the calorimetric separation of electrons and gammas to succeed, the dE/dx metric must be well reconstructed. As the charge depositions are measured discretely in 2D on single wires, in each of the wire planes we use the 3D axis of the shower to calculate an “effective” pitch (dx) between hits. This effective pitch is, in other words, the real distance in the TPC that a particle travels between its two projections (hits) on adjacent wires. Figure 6 shows the distributions of effective pitches for the electron and gamma samples. The effective pitch is at least the wire spacing, which is 0.4 cm in ArgoNeuT. The gamma distribution shows a slightly higher effective pitch, which is expected from Figure 17 showing that the gammas are at slightly higher angles to the wire planes than the electron sample. In the calculation of dE/dx , the effective pitch is used as the estimate of dx .

A valuable cross-check is the distribution of

Figure 7. Distribution of dE/dx for all hits at the start of the shower for the electron and gamma samples using Monte Carlo.

every dE/dx deposition measured at the start of the shower. Figure 7 shows the distributions for the Monte Carlo simulation of both electrons and gammas. The electron hits follow a Gaussian-convolved Landau distribution peaked at the dE/dx value corresponding to one single ionizing particle. The gamma distribution peaks at a value corresponding to two single ionizing particles, but is more complicated due to the presence of gammas that Compton scatter instead of pair producing (seen at approximately 2 MeV/cm in Figure 7).

For the gamma sample, the comparison of data and simulation is shown in Figure 8. Since the gamma sample is produced entirely by selecting showers with a displaced vertex, the purity of the gamma sample is taken to be nearly 100% in this analysis.

For the electron sample, we can not assume that the purity of the sample is 100% based on topology alone. As seen in Figure 3, a non-negligible amount of gammas will convert at a sufficiently short distance that they will get selected as electrons in a topological based cut. Hadronic activity at the vertex can also obscure the presence of a gap from a gamma. Therefore, the distribution of electron-like dE/dx hits analogous to Figure 8 is expected to be modeled by a combination of electron and gamma showers in Monte Carlo.

Figure 8. Distribution of dE/dx for all hits at the start of the shower for the gamma sample.

The electron and gamma distributions from Figure 7 are used to fit the equivalent distribution of the electron-candidate data sample, using a linear combination of electron and gamma Monte Carlo such that the normalization is fixed. The χ^2/dof is minimized between the (area normalized) data distribution and the combination of the electron and gamma distributions from Monte Carlo. The best fit is shown in Figure 9. The χ^2/dof decreases from 2.78 with no gamma contamination to 1.02 when a gamma contamination is included at $20 \pm 15\%$. This represents a direct measurement of the misidentification rate of the topological selection of electrons for this particular analysis, and demonstrates a method to measure this mis-ID rate in future electron neutrino searches in LArTPCs.

As a final verification of the reconstruction, the measured distribution for the electron candidates is corrected by subtracting the gamma distribution from Figure 9, scaled by the 20% found above. This background subtracted distribution is fit with a Gaussian-convolved Landau distribution to determine the most probable value of charge deposition. In particular, the most probable value of dE/dx for electron like hits is consistent with the theoretical values as shown in Figure 10. For electrons above 100 MeV/c, as this sample is, the theoretical expectation of the most probable ionization is 1.77 MeV/cm. This is in good agreement with the fitted value of 1.74 MeV/cm.

Figure 9. dE/dx for all the hits from the electron candidate data sample, compared to a sample of Monte Carlo comprised of 80% electrons and 20% gamma.

VI. DETECTION OF ELECTRON NEUTRINOS

The sample of electron candidate events is expected to be exclusively from ν_e CC events. As a validation, we have studied the kinematic behavior of the electron-candidate sample. Due to the small active volume of the ArgoNeuT detector, the electromagnetic showers are poorly contained and the initial electron energy is not a measurable quantity. Instead, we measure the distribution of reconstructed *deposited* energy, and we compare it to a simulation of electron neutrino events. The flux used to simulate the electron neutrino events is computed with a simulation of the NuMI beam with FLUKA [33]. The electron neutrino and anti-neutrino flux for NuMI in anti-neutrino mode is shown in Figure 11 ($\langle E_{\bar{\nu}_e} \rangle = 4.3$ GeV, $\langle E_{\nu_e} \rangle = 10.5$). The electron neutrino and anti-neutrino flux is predominately electron anti-neutrinos.

Figure 12 shows the kinematic distribution of the electron events' deposited energy and angle θ , both calculated as described in Appendix A. Both the deposited energy and reconstructed angle are area normalized independently for both data and simulation. In both distributions, the data has not been corrected

Figure 10. (Top) Background subtracted distribution of the hits at the start of the electron showers, with a fitted Gaussian-convolved Landau . (Bottom) Most probable value of ionization as a function of momentum for electrons traversing liquid argon.

to account for the 20% contamination of photons, and the simulation does not account for this. However, the distributions are presented as a demonstration that the electron candidate sample is modeled by the Monte Carlo, despite the low statistics and other deficiencies.

Due to the fact that the electron candidate events were selected manually from a sample of showering events, we are unable to accurately estimate the efficiency of electron neutrino selection. Therefore, an absolute comparison of data and Monte Carlo is not possible, and not presented here. For the same reason, the measurement of the electron neutrino scatter cross section is also not presented. In a subsequent publication, we will measure the selection efficiency and report the electron neutrino scattering cross section on argon.

Figure 11. Electron neutrino and anti-neutrino flux from the NuMI beam in anti-neutrino mode at the ArgoNeuT detector.

Figure 12. Kinematic distributions of deposited electron energy (top) and angle with respect to the beam (bottom). Error bars represent statistical uncertainty only.

VII. dE/dx SEPARATION

Once an electromagnetic shower has been identified and reconstructed, the information from the charge depositions at the start of the shower needs to be aggregated into a single dE/dx metric in order to separate electrons from gammas with calorimetry.

In the previous section, the conversion from dQ/dx (the measured charge per unit centimeter), to dE/dx (deposited energy per unit centimeter) is computed using a nonlinear model of the recombination of electrons and argon ions [34] [32]. In considering the ionization at the start of a gamma induced shower where an electron and positron pair are present, we assume the ionization clouds of the two particles are sufficiently separated such that a non-linear model incorrectly inflates the dE/dx from a dQ/dx , for higher values of dQ/dx . Thus, the dE/dx separation is computed using a minimally ionizing particle scale recombination correction for all charge depositions at the beginning of the shower in the electron and gamma samples. While this is not applicable for highly ionizing fluctuations, it prevents an over estimation of the dE/dx of gammas which artificially inflates the calorimetric separation power.

For a given event there is not a statistically large sample of energy depositions to use for measuring a robust average dE/dx . Given the Landau nature of the energy deposition fluctuations away from the most probable value, it is not surprising that an aggregate metric will tend towards higher energy depositions per centimeter than the most probable value. For this analysis, when computing the dE/dx separation metric for a shower all of the hits within a rectangle of 4 cm along the direction of the shower and 1 cm perpendicular to the shower are collected, and the median is computed. Details about this choice of dE/dx calculation are found in Appendix B.

Results of the dE/dx measurement of electrons and gammas are shown in Figure 13. This Figure represents the first demonstration of the calorimetric separation of electrons and gammas in a LArTPC using neutrino events. De-

Figure 13. The dE/dx distribution for electrons (blue) and gammas (red). The solid blue curve, representing the simulation of electron dE/dx , includes a 20% contamination of gammas consistent with the results from Figure 9.

spite the low statistics of the ArgoNeuT experiment, the electron and gamma separation using calorimetry is clearly validated. For example, when a cut is made at 2.9 MeV/cm we find a $76 \pm 7\%$ efficiency for selecting electron candidate events in data with a $7 \pm 2\%$ contamination from the gamma sample. Here, the uncertainties on the efficiency are estimated with the Feldman-Cousins method [35] and are statistical only. It must be noted, however, that the sample of electron candidates in this figure is not background subtracted. The efficiency to select electrons with the same cut at 2.9 MeV/cm, estimated with the Monte Carlo, is 91%. This is consistent with the above measurement that $20 \pm 15\%$ of the electron candidate sample, selected by topology only, is in fact gammas.

The value of the cut used above, 2.9 MeV/cm, is also somewhat arbitrary and must be determined uniquely for each analysis. In this

case, it is selected as the mid point between the two peaks of the distribution. However, in an analysis targeting electron neutrinos the absolute normalization of the electron and gamma shower populations is crucial. The desired purity of electrons must be balanced with the need to keep sufficient electron statistics. An aggressive dE/dx cut, at 2.5 MeV/cm, effectively rejects gammas but also can remove a significant amount of electrons (here it removes 30% of electron candidate events in data, 13% of Monte Carlo electrons). Though this paper represents a demonstration of the calorimetric separation of electrons and gammas through dE/dx , it is strongly recommended to evaluate the precise values of the dE/dx cut for future analyses.

VIII. CONCLUSIONS

We have analyzed a sample of neutrino events acquired by the ArgoNeuT detector and selected a sample of electron-neutrino candidate interactions and gammas originating from neutral current and charged current muon-neutrino interactions.

The high granularity of a LArTPC allows precision topological discrimination of gammas and electrons. A purely topological cut produced a sample of electron neutrino events with an estimated $80 \pm 15\%$ purity. This is the first analysis to identify and reconstruct a sample of low energy electron neutrinos in a LArTPC. The detection and characterization of these electron neutrino and anti-neutrino events is an essential step towards the success of large scale LArTPCs such as DUNE and the SBN Program.

Additionally, we have shown that a metric based on the dE/dx deposition in the initial part of the shower is valid method of separating electron-neutrino charged current events from gamma backgrounds, shown in Figure 13. The full gamma background rejection capability of liquid argon detectors will be enhanced by adding to this a topological cut. Further, full reconstruction of an event can improve gamma rejection. For example, identification of two electromagnetic showers that reconstruct with an invariant mass consistent with the π^0 mass can remove both showers from the electron candidate sample, even if there is not a gap present and the dE/dx cut fails. This work represents the first experimental proof of applying a calorimetric cut to separate electrons from gammas in a liquid argon detector using neutrino events.

One should note that the efficiency and misidentification rates presented here do not represent the full capability of liquid argon TPCs to discriminate gamma backgrounds from electron signals. The final separation power of LArTPCs leverages multiple identification techniques, of which calorimetry is just one. Further, the exact efficiencies and misidentification rates depend heavily on the energy spectrum of the electromagnetic showers: the Compton scattering gammas, a major source of impu-

rity, appear predominately at energies below 200 MeV.

IX. ACKNOWLEDGEMENTS

ArgoNeuT gratefully acknowledges the cooperation of the MINOS collaboration in providing data for the use in this analysis. We would also like to acknowledge the support of Fermilab (Operated by Fermi Research Alliance, LLC under Contract No. DeAC0207CH11359 with the United States Department of Energy), the Department of Energy, and the National Science Foundation in the construction, operation and data analysis of ArgoNeuT. A.S. is supported by the Royal Society. G.S. is supported by a Fermilab Neutrino Physics Center Fellowship.

Appendix A: Electromagnetic Shower Reconstruction

Figure 14. Diagram of the 3D start point algorithm.

The conventional coordinate system in LArTPC reconstruction algorithms assigns the Z direction to the direction of the beam, the Y direction as the vertical direction (bottom to top of the TPC), and the X direction in the drift direction such that the coordinate system is right handed. The 3D start point is initially

calculated from the intersection point of the wires where the two 2D start points are found and their position in the drift time coordinate. The start point in 3D is improved using an iterative algorithm, and illustrated in Figure 14.

An initial guess, the point in black, is made for the start point based on the 2D start points (yellow stars in each plane). The start point in 3D is projected into each plane, and the error in the 3D start point is the sum (over each plane) of the distance between the input 2D start point in each plane and the projection of the 3D point. Six additional points, along the detector coordinates (in the $\pm x$, y , and z directions), are also projected into each plane, and the error of each point is computed similarly (black dashed lines show the distance between projection and true start point). The point with the smallest summed error is chosen as the improved 3D start point, and the algorithm makes an additional six guesses around it. If the central point (in black) is chosen as the best fit point, the distance the other 6 points are offset from it is decreased and the algorithm repeats. This procedure is repeated until the algorithm can no longer improve the accuracy of the 3D start point. The initial offset from the central point for the 6 auxiliary points is 5 centimeters, and it decreases by 2% for each successful iteration. As seen in Figure 16, the 3D start point resolution is generally better than 1 cm.

Figure 15. Diagram of the 3D start direction algorithm.

Similar to the 3D start point, the 3D axis is computed using an iterative projection matching algorithm. The standard TPC trigonometric formula is used to compute an approximate 3D axis based on the angle of each shower in the collection and induction plane:

$$\theta = \arccos \frac{m}{\sqrt{l^2 + m^2 + n^2}}, \quad (\text{A1})$$

$$\phi = \arctan \left(\frac{n}{l} \right) \quad (\text{A2})$$

where

$$l = \text{sign}(t_{\text{end}} - t_{\text{start}}), \quad (\text{A3})$$

$$m = \frac{1}{2\sin(\alpha)} \left(\frac{1}{\Omega_0} - \frac{1}{\Omega_1} \right), \quad (\text{A4})$$

$$n = \frac{1}{2\cos(\alpha)} \left(\frac{1}{\Omega_0} + \frac{1}{\Omega_1} \right). \quad (\text{A5})$$

Here, θ represents the polar angle in 3D with respect to the z axis (approximately the beam direction). ϕ is the azimuthal angle in the x - z plane, with $\phi = 0$ along the z axis, and α is the angle of the wire planes with respect to the vertical direction, which in ArgoNeuT is 60 degrees. Ω_0 and Ω_1 are the tangents of the 2D angles of the shower measured in each plane. t_{start} and t_{end} are the start and end points of the cluster measured in drift time, such that l is positive if the shower points away from the wires and negative if the shower points towards the wires.

The reconstructed 3D axis is then projected into each plane, and the slope (in 2D) is compared against the slope of the electromagnetic showers in each plane. Based upon the quality of the match between the projection and the 2D slopes, the 3D axis is adjusted until the best fit is obtained - see Figure 15. An initial guess, the arrow in black, is made for the start direction based on the 2D start directions (red arrows in each plane). The start direction in 3D is projected into each plane, and the error in the 3D start direction is calculated. An additional set of 3D directions (gray arrows) are also projected into each plane. If the central direction (in black) is chosen as the best fit direction, the angular separation between it and

Figure 16. The calculated resolution of the 3D start point (top) and angular resolution (bottom) for single electromagnetic showers generated with the LArSoft package. The angular resolution for gammas is slightly worse than for electrons because the gamma sample is at lower energy, and hence has fewer depositions (hits) in the TPC.

the other (gray) directions is decreased and the algorithm repeats. This procedure is repeated until the algorithm can no longer improve the accuracy of the 3D start direction.

The angular resolution for electromagnetic showers, shown in Figure 16, is generally quite good ($< 5^\circ$) though there is a substantial tail. However, for this analysis, the poor resolution in a few measurements of the 3D axis has a minimal effect on the dE/dx calculation. This is due to the fact that the majority of the events are forward going, as shown in Figure 17. Therefore a moderate uncertainty in the 3D angle leads to only a small uncertainty in the effective wire pitch, described below, and a small uncertainty in dE/dx .

Figure 17. The distribution of the polar angle of events with respect to the Z direction (approximately the beam direction). The electron sample is very forward going, and the gamma sample has a wider distribution of angles.

Since an electromagnetic shower is a combination of many single ionizing particles - electrons and positrons - and is not composed of highly ionizing stopping particles - i.e., protons - the measured charge on the sense wires in the peak of the showering activity is a sum of many minimally ionizing particles. Therefore, to calculate the total energy deposited by an electromagnetic shower, each deposition collected is corrected by a recombination amount that is proportional to a minimally ionizing particle. All of the energy depositions, once corrected, are summed into a final measure of the reconstructed, deposited energy.

Appendix B: dE/dx Calculation Methods

While investigating the methods to convert a sample of hits (per shower) into a single variable, three promising dE/dx metrics were developed:

1. **Outlier Removed Mean:** For every hit considered for each shower (within a certain distance from the start), the mean dE/dx of the hits is calculated, as well as the RMS. The hits that are outside of the mean \pm the RMS are then rejected, and

the mean of the remaining hits is recomputed and used.

2. **Median:** The same initial set of hits as above is used. However, a median is calculated instead of rejecting outliers. In particular, this method is robust against single high or low fluctuations.
3. **Lowest Moving Average:** For the same set of N initial hits, a moving 3 hit average is calculated. For example, for N hits, the average is calculated of the hits (1,2,3), then the hits (2,3,4), etc. until the hits ($N-2$, $N-1$, N). For all of these average values calculated, the lowest value is used as the dE/dx measure. This is designed to find regions where the start of the shower is behaving as a minimally ionizing particle for an extended period.

To determine which metric is the best for separating electrons from gammas, the truth level energy depositions from the Monte Carlo simulation are examined. For each event, the true energy depositions are binned into “hits” with a pitch that corresponds to the pitch of the simulated shower on the collection plane. Then, the three dE/dx metrics above are computed for the true hits, and this processes is repeated while varying the length of the shower used in

the dE/dx calculation. The number of hits used in the calculation is a function of the distance along the shower, from the start and moving along the axis of the shower, from which the hits are collected. The distance used is varied from 2 cm up to 20 cm, with a width of 1 cm. It was found that a width 1 cm was sufficient to collect the hits along the trunk of the shower. The results are provided in Figure 18, which show that the median metric is the most robust over a variety of distances used at the start of the shower. Give this result, the median is chosen as the optimal metric for this paper.

In addition, the length of the shower used in this analysis is fixed at 4 cm. As shown in Figure 18, even the median metric begins to degrade at longer distances along the shower, though the degradation is much slower than with the other two methods. The exact distance used is not the most important parameter. Between 3 and 5 cm of distance along the shower, all distances yield equivalent separation power.

Lastly, to verify that the dE/dx calculation from the reconstruction accurately models the true dE/dx of the electromagnetic showers, Figure 19 shows the relationship between the true dE/dx and the reconstructed dE/dx . This demonstrates that the reconstructed dE/dx well reproduces the true dE/dx of each shower.

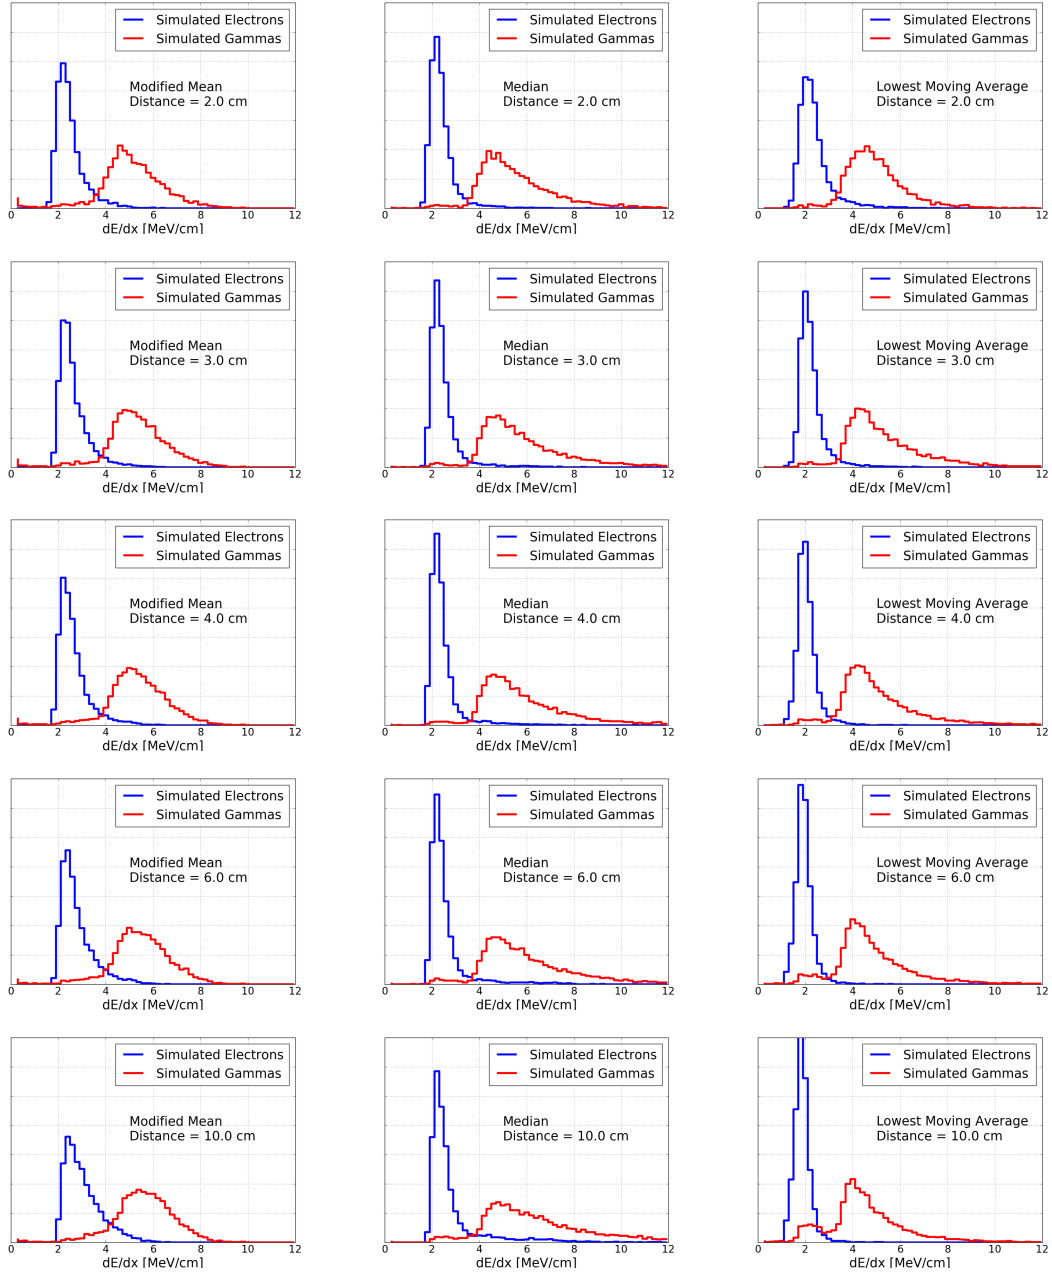

Figure 18. The separation power of the three dE/dx metrics, using a variable amount of the start of the shower in the calculation. As can be seen, all three metrics show promise at shortest distances. However, at long distances, the Modified Mean develops a large tail in the electron distribution, and the Lowest Moving Average shifts many gammas into the electron peak.

Figure 19. The true dE/dx of the beginning of simulated showers, calculated from simulated energy depositions in the TPC, vs the reconstructed dE/dx of the same showers. The electrons (left) and the gammas (right) both show a strong correlation between true and reconstructed dE/dx . There is a small offset arising from reconstruction inefficiencies, below the 10% level in both electrons and gammas.
